An Overview of the Earth System Modeling Framework

V. Balaji
SGI/GFDL Princeton University

Computing in the Atmospheric Sciences
Annecy, 9 September 2003
Talk overview

- Why frameworks have become hot: science
- Programming models for underlying hardware
- Architectural hierarchy: memory models, grids, components
- The ESMF project
Components of the climate system

**Atmosphere** atmospheric fluid dynamics and thermodynamics, moist processes, radiative transfer, transport and chemistry of trace constituents.

**Ocean** World ocean circulation, ocean biogeochemistry.

**Land surface** Surface processes, ecosystems, hydrology.

**Ocean surface** Sea ice, wave processes.
## Complexity of climate simulations

Models have grown increasingly complex with time.

Components are developed “offline” (bottom left) and then are integrated into comprehensive coupled models.
Timescales and space scales

**Clouds**  minutes to hours; 10 m – 100 km.

**Ocean eddies**  hours to days; 10 km.

**Weather patterns**  days; continent scales.

**Ocean currents**  days; ocean basin scales.

**Short-term climate**  seasonal-interannual; El Niño; monsoons.

**Climate change**  Decadal-centennial; ocean overturning and deep water formation.

**Paleoclimate**  Millennia to deep time; ice ages; orbital changes.
Discretization in space and time

Each process has its own intrinsic time and space scales.

Older models did not allow subcomponents to be on independent grids and timesteps.

- Old way: sharing of data through arrays in common blocks.

- New way: independent model grids connected by a coupler.

Each physical \textit{process} component becomes an independent \textit{code} component that can be separately instantiated, initialized, stepped forward, and terminated.
Gridded and ungridded components

Components may be associated with a grid (gridded component), associated with more than one component (coupler), or none at all (local computations, e.g. chemistry).

Each component has its own data dependencies, decomposition strategies and coupling requirements. It must be possible to take full advantage of these features in a parallel code.
Types of grids

- Spectral grids.
- Lat-lon grids.
- Logically rectangular grids in generalized curvilinear coordinates:
  - Displaced pole
  - Tripolar grids
  - Cubed sphere
- Reduced grids.
- Icosahedral and geodesic grids.
- Unstructured grids; catchment grids.
Data assimilation

Data can appear at unpredictable locations in time and space (radiosondes, buoys, satellites) and have no clear radius of influence (“location streams”).

Models will “slosh” if incompatible with data.

Data assimilation involves bringing models and data into acquiescence. Assimilation algorithms can be treated as gridded components.
Model sizes and times

**Climate** Typically measured in simYears/wallDay. Resolution is adjusted till an experiment runs within a time useful for research. Current high-end research: $\sim 10^2$ variables integrated for $\sim 10^6$ timesteps on $\sim 10^6$ gridpoints. (Earth Simulator considerably raises this bar, but there is currently no relevant experience to compare against).

**Weather** Operational forecasting is measured in simHours/wallHour. Resolutions about $4 \times 4$ higher; $\sim 10^3$ timesteps.
Data exchange

Data exchanges between components take the form of fluxes of heat, momentum and tracers.

Conservation is very important for climate models; less so for weather.
Memory models

**Shared memory** signal parallel and critical regions, private and shared variables. Canonical architecture: UMA, limited scalability.

**Distributed memory** domain decomposition, local caches of remote data (“halos”), copy data to/from remote memory (“message passing”). Canonical architecture: NUMA, scalable at cost of code complexity.

**Distributed shared memory or ccNUMA** message-passing, shared memory or remote memory access (RMA) semantics. Processor-to-memory distance varies across address space, must be taken into account in coding for performance. Canonical architecture: cluster of SMPs. Scalable at large cost in code complexity.
Uniform interface to memory models: DEs and Layouts

**Decomposition Element** A DE is the logical atom of a distributed object, which may or may not map onto a single PE.

**Layout** A layout describes how DEs are organized along some logical dimensions. We may choose to map these dimensions on to shared and distributed memory.

**Machine model** A machine model describes the hardware and applicable memory semantics: a description of the architecture in terms of aNodes and mNodes.
Uniform interface to the grid index space: the \texttt{distGrid}

A \texttt{distGrid} describes how to distribute the index space of a component across a DE layout, and most importantly, the \textit{data dependencies} between DEs.

Halo updates and redistributions are typical operations performed using \texttt{distGrids}.
Overlay physical information on the distGrid:

physGrid

All the model numerics require knowledge of the physical locations, orientations, and interrelations of array indices.

Differential operators (gradient, divergence) are typical operations requiring physGrids.
Interpolate data between grids: \texttt{reGrid}

When components on independent \texttt{physGrid}s must exchange data, they require a \texttt{reGrid}.

On parallel systems, we require all calls to be local; the \texttt{reGrid} object contains the optimized \texttt{routes} for communication.
Fields and bundles

Alongside the grid information, each model variable is present as a distributed array. It is useful, indeed essential, to associate metadata that describe the physical content (name, units, grid locations, range of valid values) of the array. All this information together comprises a model Field.

Fields that share a grid may be treated collectively for certain grid operations. A collection of fields sharing a grid is called a bundle.
Model composition

We develop a hierarchy of components and assign them to PEs as appropriate.

A coupler mediates between pairs of components needing to exchange data, and matches fields in their import and export States.

The coupler runs on the union of PEs of its components.
Architecture of an Earth System Modeling Framework: the sandwich

- Coupler layer
- Model layer
- Fields and grids
- Low-level kernels

ESMF

The Earth System Modeling Framework is an end-to-end solution for the problem outlined here: supporting distributed development of models with many interacting components, with independent space and time discretization, running on complex modern scalable architectures. A capsule history of ESMF:

- The need to unify and extend current frameworks achieves wide currency (c. 1998).
- NASA offers to underwrite the development of an open community framework (1999).
- A broad cross-section of the community meets and agrees to develop a concerted response to NASA uniting coupled models, weather, and data assimilation in a common framework (August 1999). Participants include NASA/GMAO, NOAA/GFDL, NOAA/NCEP, NCAR, DOE, and universities with major models.

- Funding began February 2002: $10 M over 3 years.
- Second Community Meeting, Princeton, May 2003: design review.
ESMF features

- ESMF is usable by models written in f90/C++.
- ESMF is usable by models requiring differentiability.
- ESMF is usable by models using shared or distributed memory parallelism semantics.
- ESMF supports serial and concurrent coupling.
- ESMF supports multiple I/O formats (including GRIB/BUFR, netCDF, HDF, native binary).
- ESMF has uniform syntax across platforms.
- ESMF runs on many platforms spanning desktops (laptops, even!) to supercomputers.
Language interoperability

Models increasingly are built to use high-level abstract language features (f90, C++) to facilitate development process across large teams. ESMF is written to be usable by models written in both languages.

Incompatibilities:

- Languages use entirely different memory semantics. ESMF distinguishes between “deep” and “shallow” objects: depending on whether memory is managed by callee or caller.

- High-level data structures do not cross language boundaries. ESMF implements cross-language data structures by implementing an intermediate layer in a low-level language (f77, C) where intrinsic datatypes can be cross-matched. This includes a unique implementation allowing f90 array pointers to be manipulated in either language.

The ESMF **Implementation Report** presents details of its cross-language technology.
Link to data frameworks

Community data frameworks are under development. For model output data to be scientifically useful, the researcher must have some knowledge of how the data was produced. Model data requires a *model’s eye view* description of the data, another layer of metadata, which includes:

- Description of model components: e.g. FMS BGRID atmosphere, land and sea ice coupled to MITgcm ocean.
- Description of grid configurations and resolutions.
- Choice of physics packages and input parameters.
- Model state and its fields.

ESMF and PRISM are emerging standards that allow the development of the model metadata layer, based on the state data structures and its base classes. Modeling framework data structures map directly on to community hierarchical metadata.
Summary

- The Earth System Modeling Framework supports distributed development of models with many interacting components, with independent space and time discretization, running on complex modern scalable architectures.

- Prototype release scheduled for May 2004.

- Future maintenance guarantee from NCAR: seeking funding for further development.

- Future directions: link to community data portals, enable new scientific applications, runtime environment.
